Volatility Risk Premium and Non-Directional Option Strategies on the S&P 500 Index: Evidence from 2010–2023 Option Chains

Giordano Margotti*

November 2026

Abstract

This paper tests, on daily chains of European options on the S&P 500 index from 2010 to 2023 (3,499 sessions, 47,699 date–expiry pairs), whether a volatility risk premium exists and whether non-directional option-selling strategies capture it net of costs. The answer depends on the measure. The 30-day model-free implied volatility exceeds subsequently realized volatility by +3.45 points on average (t-statistic 6.48), whereas at-the-money implied volatility exceeds it by only +0.72 points (t 1.36): the premium sits in the wings of the distribution, in out-of-the-money puts in particular, not in the central level of the surface. The at-the-money premium is significant in 2010–2014 and statistically zero in the two following sub-periods. Across 434 configurations of ten strategy families (1,310,509 simulated trades), the median Sharpe ratio is +0.39 at mid prices and -0.40 at bid-ask prices; the share of configurations with a significantly positive alpha against the index falls from 16.4% to 2.5%. Positive results are concentrated in structures that sell puts and are largely explained by equity market exposure. The evidence is consistent with a premium that exists as compensation for tail risk, but that the bid-ask spread and ex-post parameter selection make hard to capture systematically.

Keywords: volatility risk premium, implied volatility, index options, iron condor, put credit spread, GJR-GARCH, transaction costs, multiple testing.

1 Introduction

The project behind this document explores the possibility of generating excess returns through non-directional option strategies, that is, strategies whose result does not depend on the direction of the underlying as long as the price stays within a range or volatility remains contained. These are premium-selling strategies: iron condors, strangles, put credit spreads and related structures. The project's framing document identifies three sources of expected return: range-bound behavior of the price, the time decay of option value, and the existence of a volatility risk premium (VRP), namely a systematic difference between the volatility implied by option prices and the volatility the underlying subsequently realizes.

The first two are not expected returns in a strict sense. Time decay is the price of exposure to convexity: in a market where options are fairly priced, the theta collected offsets gamma losses on average. Range-bound behavior is already embedded in the premium. The only source of positive expected return for an option seller is therefore the third: an option price above the expected value of its payoff under the real-world measure. The research question is accordingly twofold:

1. whether the volatility risk premium exists in the data, how large it is, in which region of the volatility surface it lies and how stable it is over time;

*The starting code base and the data archives come from the joint work of the *finance-thinking* group (repository `options_strategy`). All analyses in this document were recomputed from the option chains; errors and omissions are the author's own. This document is for research purposes and is not investment advice.

2. whether the non-directional strategies examined by the project capture it, once the bid-ask spread, commissions, margin and the number of configurations tried are taken into account.

The contribution is empirical. All statistics are computed on end-of-day quotes of SPX options from January 4, 2010 to December 29, 2023, with a deliberately simple and reproducible design: implied volatility obtained from prices with the Black (1976) model on the forward implied by put-call parity, model-free implied variance with the Cboe formula, realized variance up to the expiry of the same option, and a GJR-GARCH(1,1) forecast with Student-t innovations estimated on an expanding window with no look-ahead. Code and results are published in the repository together with an interactive site for exploring every configuration.

The document is organized as follows. Section 2 summarizes the literature on the existence, causes and persistence of the premium. Section 3 describes data and method. Section 4 presents the evidence on the premium; Section 5 the strategy backtests; Section 6 the robustness checks and the multiple-testing correction. Section 7 documents the checks on the pre-existing code. Sections 8 and 9 discuss limitations and conclusions.

2 Literature

2.1 Definition and evidence

The variance risk premium is the difference between the expected future variance under the risk-neutral measure and its expectation under the real-world measure. The first term is observable: Britten-Jones and Neuberger (2000) show that risk-neutral expected variance can be replicated with a static portfolio of options across all strikes, with no model assumption; Jiang and Tian (2005) study its information content, and the VIX index is its market implementation. Carr and Wu (2009) build synthetic variance swap rates for indices and individual stocks and document that, for US equity indices, implied variance systematically exceeds realized variance: variance sellers earn a large and statistically significant average premium. Bakshi and Kapadia (2003) reach the same conclusion with a different strategy, showing that the gain of a purchased, delta-hedged option is negative on average. Coval and Shumway (2001) find strongly negative average returns for zero-delta straddles, and Bondarenko (2014) quantifies the historical cost of index puts: average monthly losses of several tens of percent for out-of-the-money puts. Bollerslev, Tauchen and Zhou (2009) further show that the difference between implied and realized variance predicts equity returns at the quarterly horizon, which qualifies it as a measure of the price of risk rather than a mere forecast error.

2.2 Why the premium would exist

The proposed explanations fall into three groups.

Compensation for systematic risk. Variance rises when markets fall; a security that pays in those states has insurance value and its seller must be compensated. Bates (2000) documents that, after the 1987 crash, option prices persistently embed the fear of negative jumps. Todorov (2010) and Bollerslev and Todorov (2011) attribute the larger part of the premium to compensation for jump risk, that is, to the tails, rather than to diffusive volatility. Dew-Becker, Giglio, Le and Rodriguez (2017) show that the price of risk is concentrated on very short-term realized variance, while news about future variance is priced close to zero.

Hedging demand and intermediary constraints. Bollen and Whaley (2004) link the shape of the volatility smile to the net buying pressure on index puts. Gârleanu, Pedersen and Poteshman (2009) build a model in which intermediaries cannot hedge perfectly and end-user demand moves option prices in proportion to the unhedgeable risk. In this framework the premium is the compensation of those who provide balance-sheet capacity, and it varies with it.

Preferences and perceptions. Jackwerth (2000) recovers from options an implied risk aversion that is incompatible with standard preferences after 1987; Ilmanen (2012) summarizes the evidence that, across asset classes, selling insurance against tails has been rewarded and buying lottery-like exposures has been penalized.

2.3 The efficiency view

A positive average premium does not contradict market efficiency in the sense of Fama (1970): a positive expected return for bearing systematic risk is an equilibrium price, not an anomaly. The relevant question is whether the premium exceeds the compensation justified by the risk and whether it can be captured.

On both points the literature offers reasons for caution. Broadie, Chernov and Johannes (2009) show that very negative average put returns are not, by themselves, evidence of mispricing: standard models with stochastic volatility and jumps generate returns of that order, and available samples are too short to distinguish a high premium from the absence, in the sample, of the rare events that justify it. Santa-Clara and Saretto (2009) show that margin requirements and transaction costs drastically reduce the returns actually obtainable from selling options: an investor must hold substantial cash to survive margin calls, and the implementable strategy is a fraction of the theoretical one. Constantinides, Jackwerth and Savov (2013) document that the usual risk factors do not explain index option returns without adding specific jump and volatility factors. Jurek and Stafford (2015) show that the return profile of many alternative funds can be replicated by selling index puts and that, valued at the cost of capital appropriate for that tail risk, the apparent alpha disappears. Israelov and Nielsen (2015) decompose the return of covered-call strategies into equity exposure, short volatility exposure and unintended timing, and show that most of the return is equity beta.

On the forecasting side, more recent work has rehabilitated implied volatility. Canina and Figlewski (1993) found no information content; Christensen and Prabhala (1998), with non-overlapping samples, show that implied volatility is a nearly unbiased and efficient forecast of realized volatility; the survey by Poon and Granger (2003) confirms that implied volatility generally outperforms time-series models.

Finally, the premium is not constant. Dew-Becker and Giglio (2023, 2025) document that over the last fifteen years index option alphas have become statistically indistinguishable from zero and that the variance risk premium has shrunk, consistent with a model in which option prices are determined by intermediaries and the cost of hedging has declined. For same-day expiries, Beckmeyer, Branger and Gayda (2023) estimate that retail investors lost in aggregate on zero-days-to-expiry SPX options, largely because of trading costs.

2.4 Implications for the project

Four predictions that can be tested on the available data follow from the literature: (i) the premium measured with model-free variance must be larger than the one measured on at-the-money volatility, because the larger part is compensation for the tails; (ii) the distribution of the realized premium must be strongly left-skewed; (iii) the premium must be weaker in the recent part of the sample; (iv) the returns of selling strategies must shrink markedly once costs and equity market exposure are considered. The following sections test them one by one.

3 Data and method

3.1 Data

The source is the archive of end-of-day SPX option quotes contained in the working group's repository: monthly files from January 2010 to December 2023, with one row per expiry–strike pair and, for each

side, bid, ask, the vendor's implied volatility and Greeks. The archive contains 3,499 sessions; the only gap longer than five calendar days falls in January 2011. The analyses use expiries with 1 to 75 calendar days to expiry. The index level is the one reported in the chains at the close.

SPX options are European and cash-settled; the multiplier is 100. Dollar results refer to one SPX contract; for the XSP contract, one tenth the size, values are divided by ten, while per-contract commissions are unchanged and therefore weigh ten times more in relative terms.

3.2 Forward, implied volatility and delta

For each date–expiry pair the implied forward F is obtained from put-call parity at the strike where call and put mid prices are closest: $F = K^* + C(K^*) - P(K^*)$. Dividends and rates thus enter through the market and require no external assumption; the discount factor on the premium, negligible at the maturities considered, is set to one. The implied volatility of each option is obtained by bisection on the Black (1976) formula applied to the mid price, with T equal to calendar days divided by 365; delta is the forward delta of the same model. At-the-money volatility is the linear interpolation in strike, at $K = F$, of the volatilities of out-of-the-money options.

The integrity checks give the expected results: the inversion reproduces prices with a maximum error of the order of 10^{-5} index points; at $K = F$ the implied volatilities of put and call coincide (zero median difference, 5th and 95th percentiles within a tenth of a volatility point); call delta minus put delta equals one; the cost of carry implied by the forward is consistent with the level of rates net of dividends year by year.

3.3 Model-free implied variance

Model-free implied variance follows the VIX formula applied to the single expiry:

$$\sigma^2_{\mathrm{MF}} = \frac{2}{T}\sum_i \frac{\Delta K_i}{K_i^2} Q(K_i) - \frac{1}{T}\left(\frac{F}{K_0} - 1\right)^2, \tag{1}$$

where $Q(K_i)$ is the mid price of the out-of-the-money option with strike K_i, K_0 is the first strike not above F and the sum stops, on each side, after two consecutive zero bids. The mean of σ_{MF} on the expiry closest to 30 days is 18.06%, in line with the order of magnitude of the VIX index over the period.

3.4 Realized variance and definition of the premium

For an option observed at t with expiry at $t+T$, realized variance is the sum of squared daily log returns from the session after t to expiry, divided by T in calendar years:

$$RV_{t,T} = \frac{1}{T}\sum_{s=t+1}^{t+T} r_s^2. \tag{2}$$

Implied and realized are thus annualized over the same calendar interval and refer to exactly the same period. The premium is reported in three forms: in volatility points on the at-the-money measure, $\sigma_{\mathrm{ATM}} - \sqrt{RV}$; in volatility points on the model-free measure, $\sigma_{\mathrm{MF}} - \sqrt{RV}$; in variance units, $\sigma^2_{\mathrm{MF}} - RV$, which corresponds to the payoff of a short variance swap.

For each target horizon (7, 14, 21, 30, 45 and 60 days) the expiry with time to expiry closest to the target, within a preset tolerance, is selected in every session. Since daily observations overlap, standard errors are Newey and West (1987) with a number of lags equal to one and a half times the horizon in sessions; statistics on the non-overlapping sample are reported as a check.

3.5 GJR-GARCH forecast

The reference model for expected volatility under the real-world measure is the GJR-GARCH(1,1) of Glosten, Jagannathan and Runkle (1993) with Student-t innovations, an asymmetric generalization of the models of Engle (1982) and Bollerslev (1986):

$$\sigma_{t+1}^2 = \omega + \left(\alpha + \gamma \mathbf{1}_{\{\varepsilon_t<0\}}\right) \varepsilon_t^2 + \beta\, \sigma_t^2. \tag{3}$$

Estimation uses an expanding window of at least 504 sessions and is repeated every 21 sessions; between estimations the conditional variance is updated with the current parameters and only with returns already observed. The forecast of total variance to expiry is the sum of daily forecasts over the n remaining sessions, $\sum_{k=1}^{n}\left[\bar{\sigma}^2 + p^{k-1}(\sigma_{t+1}^2 - \bar{\sigma}^2)\right]$, with persistence $p = \alpha + \gamma/2 + \beta$ and long-run variance $\bar{\sigma}^2 = \omega/(1-p)$, annualized over the same calendar time as the implied measure. No correction factor is applied. Forecasts are available from January 2012. In the estimated parameters α is zero and γ lies between 0.24 and 0.36: in the sample, variance reacts only to negative returns.

3.6 Backtest design

In every session and for each target expiry (7, 14, 30 and 45 days) a unit position is opened for each configuration. Strikes are chosen by delta (0.10, 0.16, 0.20 and 0.30 for short legs); the wings of defined-risk structures follow two alternative rules: delta 0.05, or a distance equal to 1% of spot. There are ten families: short put, short strangle, short at-the-money straddle, put credit spread, call credit spread, iron condor, iron butterfly, long put, debit put spread and long at-the-money calendar. For credit structures three management rules are considered: hold to expiry; close when profit reaches 50% of the credit; close at 50% profit or at a loss equal to 200% of the credit. Exit conditions are evaluated on daily closing mid prices. In total there are 434 configurations and 1,310,509 simulated trades.

Execution prices. For each trade the result at mid prices and the sum of the half bid-ask spreads of the legs traded, at entry and at any early exit, are recorded. The result is therefore a linear function of the share x of the spread paid: $x = 0$ corresponds to mid prices, $x = 1$ to selling at the bid and buying at the ask. At expiry, settlement is in cash and involves no spread. The commission is one dollar per leg per contract.

Margin and return. For defined-risk structures the margin is the maximum loss; for naked positions it is 20% of notional, as in the group's code; for debit structures it is the premium paid. The return of each trade is the result divided by the margin. To obtain a monthly series comparable across maturities a constant-capital ladder is assumed: capital is split equally among positions open at the same time, so that each trade contributes to the return of its closing month by its return on margin divided by the number of sessions in the horizon. Monthly series are summed without compounding; mean return and maximum drawdown therefore scale linearly with the share of capital committed to margin, while the Sharpe ratio does not depend on it.

Market exposure. For each configuration the monthly returns are regressed on the monthly returns of the index; the annualized intercept (alpha) measures the return not explained by equity exposure.

4 The volatility risk premium in the data

4.1 Average level by horizon

Table 1 reports, for each horizon, the mean of at-the-money implied volatility, model-free volatility and realized volatility, with the two measures of the premium.

Three facts emerge. First, model-free volatility exceeds realized volatility by more than three points at all horizons, with t-statistics between 5.50 and 13.33. Second, at-the-money volatility exceeds realized

Table 1: Implied and realized volatility by horizon, SPX 2010–2023. Values in percentage points of annualized volatility; t with Newey-West standard errors.

		Means			ATM − realized			MF − realized			
Days	Sessions	ATM	MF	Real.	Mean	t	% > 0	Mean	t	Skew	Min.
7	2,892	15.18	17.09	13.84	+1.34	5.43	68	+3.25	13.33	−3.7	−99
14	3,018	14.98	17.25	14.10	+0.88	2.48	69	+3.15	8.98	−4.9	−90
21	3,098	15.09	17.57	14.33	+0.76	1.72	68	+3.24	7.31	−4.9	−79
30	3,134	15.32	18.06	14.60	+0.72	1.36	69	+3.45	6.48	−5.0	−77
45	3,104	15.99	19.06	15.18	+0.81	1.22	70	+3.88	5.71	−4.5	−71
60	3,250	16.30	19.57	15.34	+0.96	1.27	73	+4.23	5.50	−4.1	−64

volatility by less than one point beyond 14 days, and the difference is not statistically different from zero at 21, 30, 45 and 60 days; the at-the-money premium is significant only at 7 days (+1.34 points, t 5.43) and at 14 days (+0.88 points, t 2.48). Third, the distribution is strongly skewed. At 30 days the median at-the-money premium is +1.74 points and the premium is positive in 69.1% of sessions, but skewness is −5.0 and the minimum, in February 2020, is −77.5 points. The mean is the sum of many small gains and a few very large losses (Figure 1).

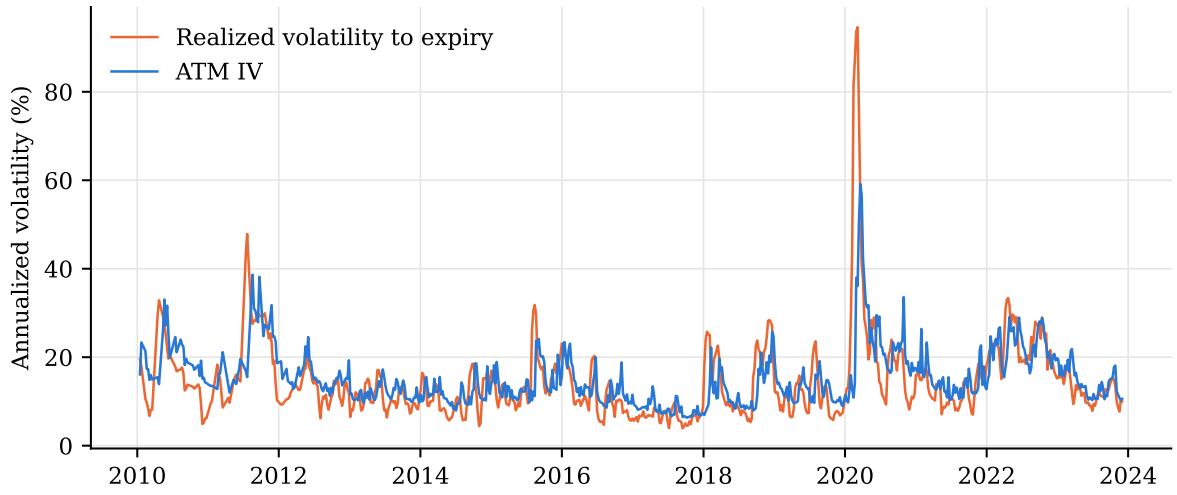

Figure 1: At-the-money implied volatility on the expiry closest to 30 days and realized volatility to that expiry. Weekly sampling.

The distance between the two implied measures, about 2.7 points at 30 days, is the contribution of the wings. In the sample the implied volatility of the 0.10-delta put exceeds at-the-money volatility by 7.34 points on average and the difference between 0.25-delta put and call is 5.48 points. The first prediction of the literature is therefore confirmed: the premium is not in the central level of the surface, it is in the skew.

4.2 Stability over time

The 30-day at-the-money premium averages +1.82 points in 2010–2014 (t 4.02), +0.46 points in 2015–2019 (t 0.84) and +0.04 points in 2020–2023 (t 0.03). Table 2 shows the yearly detail: four years out of fourteen have a negative average premium (2015, 2018, 2020 and 2022), and they are the years in which realized volatility rose abruptly. The result is consistent with the decline of the premium documented by Dew-Becker and Giglio (2023, 2025), with the caveat that three sub-periods of a few years do not allow a structural decline to be distinguished from an unfavorable sequence of events.

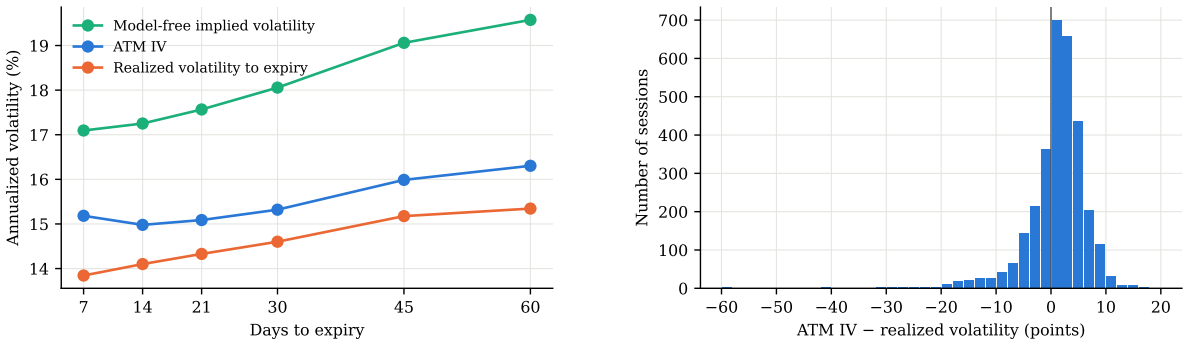

Figure 2: Left: means by horizon of the three volatility measures. Right: distribution of the 30-day at-the-money premium.

Table 2: 30-day at-the-money premium by year. Values in volatility points.

Year	Sessions	ATM IV	Realized	Premium	% > 0	Minimum
2010	108	19.96	15.86	+4.09	83	−19.0
2011	104	21.66	21.22	+0.45	65	−32.3
2012	187	15.65	12.71	+2.94	90	−1.8
2013	252	12.39	10.82	+1.57	70	−4.6
2014	249	11.89	11.06	+0.83	60	−8.2
2015	252	14.47	14.84	−0.37	62	−20.6
2016	251	13.60	11.39	+2.21	79	−7.9
2017	250	8.32	6.69	+1.64	82	−3.0
2018	252	13.08	16.01	−2.93	49	−17.2
2019	247	12.95	11.16	+1.79	77	−12.9
2020	250	24.66	27.12	−2.45	64	−77.5
2021	246	14.89	12.68	+2.22	73	−6.6
2022	256	22.56	23.75	−1.19	43	−17.9
2023	230	14.60	12.81	+1.79	83	−2.7

4.3 Implied volatility as a forecast

If the option market is informationally efficient, implied volatility must be an unbiased forecast of realized volatility, up to the risk premium. The Mincer and Zarnowitz (1969) regression, $\sqrt{RV_{t,T}} = a + b\,\sigma_t + u_t$, is the standard test: under the unbiasedness hypothesis $a = 0$ and $b = 1$.

At 30 days the estimated slope is 0.908 (standard error 0.099) and the joint hypothesis is not rejected ($p = 0.409$): at-the-money volatility is, in the sample, a statistically unbiased forecast. The same hypothesis is clearly rejected for the model-free measure at every horizon, as expected for a measure that embeds the premium for the tails. At 7 and 14 days the slope is close to one and the rejection of the joint hypothesis depends on the constant alone, that is, on the average premium. At the 45- and 60-day horizons the slope falls below one for the at-the-money measure as well: high implied volatility overstates subsequent realized volatility.

The comparison of forecasts on the 2012–2023 sample (2,920 sessions, 30-day horizon) confirms the ranking known in the literature. The root mean squared error is 7.38 points for at-the-money volatility, 8.15 for model-free, 8.26 for GJR-GARCH and 9.22 for 21-session historical volatility. In the regression that includes the three forecasts, the coefficient of implied volatility is +0.73 (t 6.50), that of GJR-GARCH +0.27 (t 1.77) and that of historical volatility −0.09 (t −1.01), with an R^2 of 0.41. The GARCH model adds marginal information of weak significance to that already contained in option prices; historical volatility adds none.

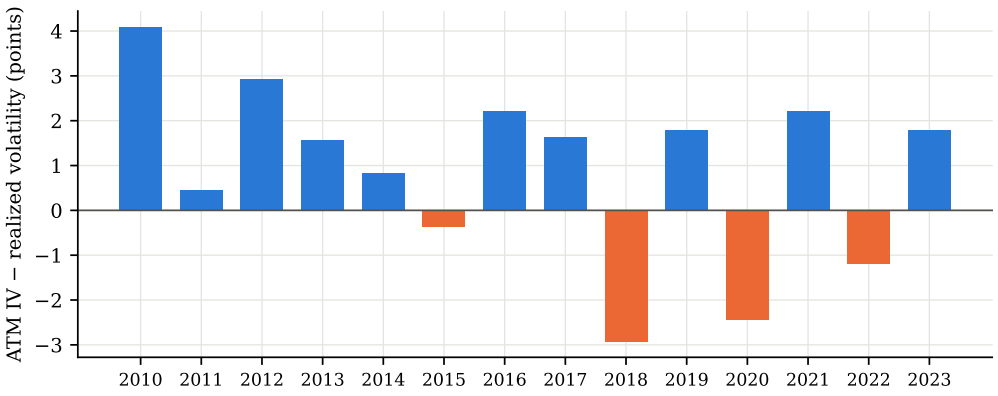

Figure 3: Average 30-day at-the-money premium by year.

Table 3: Mincer-Zarnowitz regressions of realized volatility on implied volatility. a in volatility points; p-value of the joint test $a = 0$, $b = 1$.

	ATM IV					Model-free	
Days	a	b	s.e. b	R^2	p	b	p
7	−1.35	1.001	0.084	0.60	0.000	0.959	0.000
14	−1.34	1.031	0.109	0.55	0.001	0.981	0.000
21	−0.46	0.980	0.115	0.47	0.080	0.928	0.000
30	+0.69	0.908	0.099	0.39	0.409	0.841	0.000
45	+2.14	0.816	0.071	0.31	0.035	0.737	0.000
60	+3.08	0.752	0.072	0.25	0.002	0.662	0.000

4.4 The implied-minus-GARCH signal

The project proposed the comparison between implied volatility and the GARCH forecast as an entry filter. Sorting sessions into quintiles of the difference $\sigma_{\text{ATM}} - \sigma_{\text{GARCH}}$, the mean subsequent premium is +0.00, +0.21, −0.05, +0.60 and +2.23 points from the first to the fifth quintile (Figure 4). The relation is increasing and concentrated in the last quintile; the regression of the subsequent premium on the difference has a slope of 0.21 with t 1.55 and an R^2 of 1.5%. The signal has the expected sign but does not reach conventional significance.

4.5 The price of insurance

A direct measure of the premium contained in puts is the ratio of losses at expiry to premiums collected by those who sold them (Table 4). A ratio of one corresponds to a fair price under the real-world measure. In the sample, for the 0.10-delta put the ratio is 0.44 at 30 days and 0.57 at 7 days: buyers recovered about half of the premium paid. The ratio increases toward the money (0.65 for the 0.30 delta at 30 days) and toward short maturities. This is the result of Bondarenko (2014) on a later sample. The caveat of Broadie, Chernov and Johannes (2009) applies in full: fourteen years contain a single event the size of March 2020 and none the size of October 1987.

5 Strategies

5.1 Results by family

Table 5 reports the medians by family, held to expiry, over all combinations of delta and maturity.

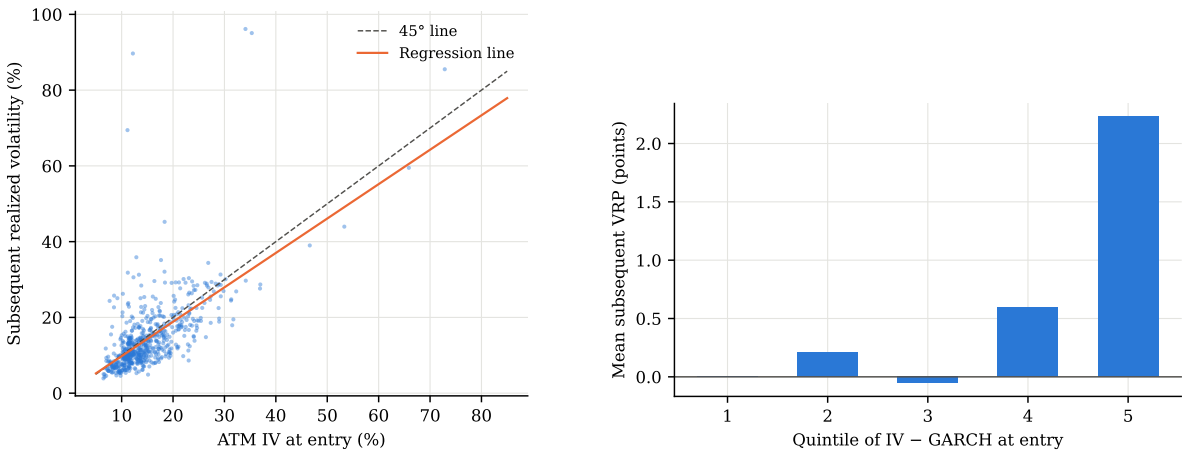

Figure 4: Left: realized volatility against 30-day at-the-money implied volatility. Right: mean subsequent premium by quintile of the difference between implied volatility and the GJR-GARCH forecast at entry.

Table 4: Puts sold and held to expiry: losses at expiry relative to premiums collected (mid prices) and share of trades finishing in the money.

	Losses / premiums by delta				% in the money	
Days	0.10	0.16	0.20	0.30	0.10	0.30
7	0.57	0.67	0.72	0.80	4.8	21.1
14	0.53	0.64	0.68	0.74	4.5	18.8
30	0.44	0.51	0.56	0.65	3.3	17.2
45	0.44	0.48	0.51	0.58	3.0	15.8

The ranking is clear and follows the location of the premium. Structures that sell puts have a positive Sharpe ratio; symmetric structures (straddle, iron condor, iron butterfly) have results close to zero at mid prices and negative at bid-ask prices; structures that sell calls have negative results, because in a rising market out-of-the-money calls were exercised more often than their price implied; structures that buy options (put, debit put spread, calendar) lose. The long at-the-money calendar has a result of about zero at mid prices and strongly negative after costs, because it requires three trades in options whose spread is wide relative to the debit invested.

Wing width is decisive. With 0.05-delta wings the spread paid by a put credit spread is about 5% of the premium traded; with wings at 1% of spot it rises to 25%, and the Sharpe ratio of the 0.20-delta, 30-day put credit spread goes from +0.83 to −0.02. Narrow structures, which are the ones accessible with limited capital, are also those on which the execution cost absorbs the whole premium.

5.2 Return and risk of the best configurations

The 0.16-delta, 45-day short put is profitable in 94% of trades, with a mean result of 885 dollars per contract and a maximum loss of 83,370 dollars: the worst loss is more than ninety times the mean gain. The Sharpe ratio is +0.93 at bid-ask prices, above that of the index over the period (0.77, price only), but beta is 0.31 and the annual alpha, +9.5% of margin capital, has a t-statistic of +1.75. The 0.20-delta put credit spread with a 0.05-delta wing at 30 days has a Sharpe ratio of +0.83, a beta of 1.14 and an alpha with t +1.58; the maximum drawdown of the series equals 93% of the capital committed to margin, which makes full deployment of capital impracticable. The 0.16-delta, 30-day iron condor has a Sharpe ratio of +0.14 and an alpha with t +0.05; the short straddle, the position closest to a pure exposure to the at-the-money premium, has a Sharpe ratio of +0.18, consistent with a statistically zero at-the-money premium.

Table 5: Medians by family, held to expiry. Annualized Sharpe ratio of the monthly series at mid and bid-ask prices; beta and t-statistic of alpha against the index; spread paid as a percentage of premium traded; share of winning trades at bid-ask prices.

In short, positive results coincide with structures that have positive beta and for which a material part of the return is equity market exposure in a period when the index returned 11.4% per year. This is the conclusion of Israelov and Nielsen (2015) and Jurek and Stafford (2015) applied to these strategies.

5.3 Exit rules

The median Sharpe ratio of credit structures is +0.41, +0.44 and +0.43 at mid prices for hold-to-expiry, 50% profit-taking, and profit-taking with a 200% loss limit respectively; at bid-ask prices it becomes −0.05, −0.44 and −0.73. At mid prices exit rules do not change expected return, as must be the case for a rule that contains no information; at bid-ask prices they worsen it, because every early exit pays a second spread, whereas cash settlement at expiry pays none. The rules reduce maximum drawdown, but at a certain cost.

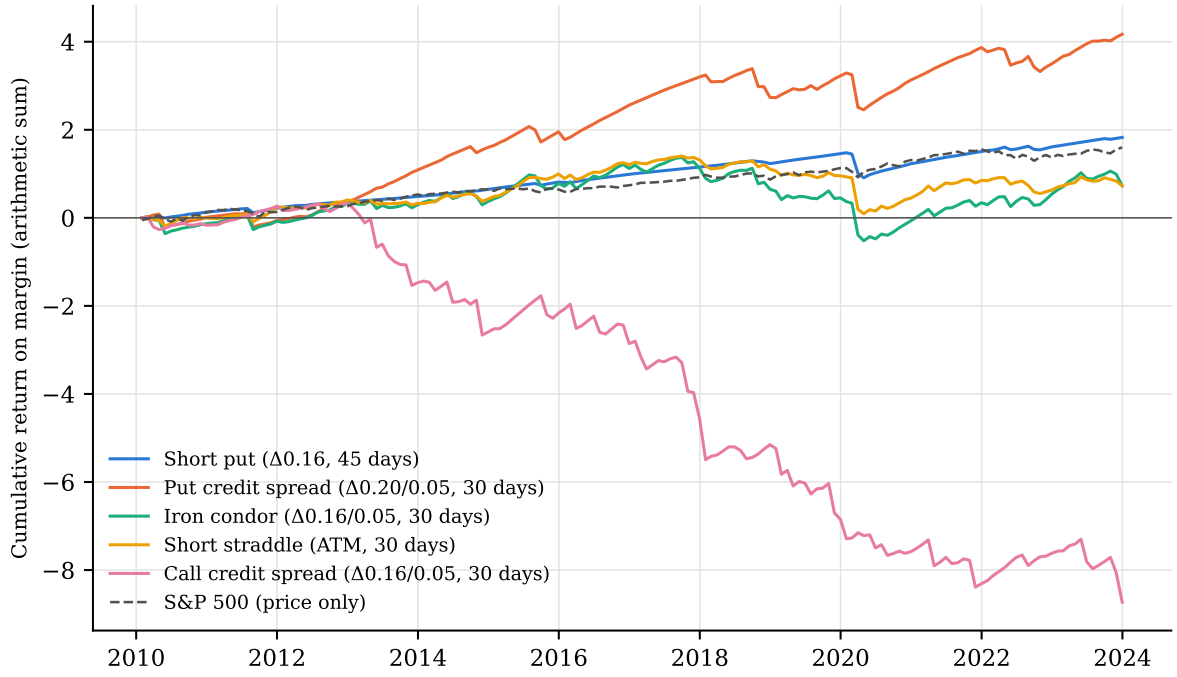

Figure 5: Cumulative return on margin (arithmetic sum of monthly returns, constant-capital ladder, bid-ask prices) for five configurations and for the index.

5.4 Entry filters

Table 7 compares, from 2012, the median Sharpe ratio without filters with the one obtained by opening positions only when implied volatility exceeds the GARCH forecast, only when it is below it, and in the extreme terciles of the level of implied volatility. The filter $\sigma_{\text{ATM}} > \sigma_{\text{GARCH}}$ improves the Sharpe ratio in 86% of credit configurations, and the median moves from -0.26 to -0.05. The improvement is systematic in sign but does not turn losing families into winning ones. For the 0.16-delta, 45-day short put the Sharpe ratio goes from +0.90 to +1.62; for the 0.16-delta, 30-day iron condor from +0.18 to +0.70. The result must be read together with that of Section 4: the signal has the correct sign, but its statistical significance on the premium is weak and the filter was evaluated on the same sample on which it was conceived.

Table 7: Median Sharpe ratio by family and entry filter, bid-ask prices, 2012–2023. Months without trades count as zero return.

Family	N	None	IV > GARCH	IV ≤ GARCH	High IV	Low IV
Short put	48	+0.88	+0.92	+0.56	+0.83	+0.28
Short strangle	48	+0.43	+0.70	+0.15	+0.37	+0.21
Put credit spread	96	+0.13	+0.24	−0.04	+0.24	−0.04
Short ATM straddle	12	+0.20	+0.41	−0.00	+0.20	+0.04
Iron condor	96	−0.85	−0.40	−0.83	−0.55	−0.30
Iron butterfly	24	−0.25	−0.06	−0.32	−0.14	−0.10
Call credit spread	96	−1.27	−0.83	−1.02	−1.00	−0.55

6 Robustness and multiple testing

6.1 Execution cost

Across 434 configurations the median Sharpe ratio is +0.39 at mid prices and −0.40 at bid-ask prices; the share of configurations with a positive Sharpe ratio falls from 64% to 38% (Figure 6). The actual execution price lies between the two extremes: closing quotes overstate the spread typical of the middle of the session, but a mid-price order on a multi-leg structure has no guarantee of execution. The site lets the share of spread paid be set and recomputes every statistic.

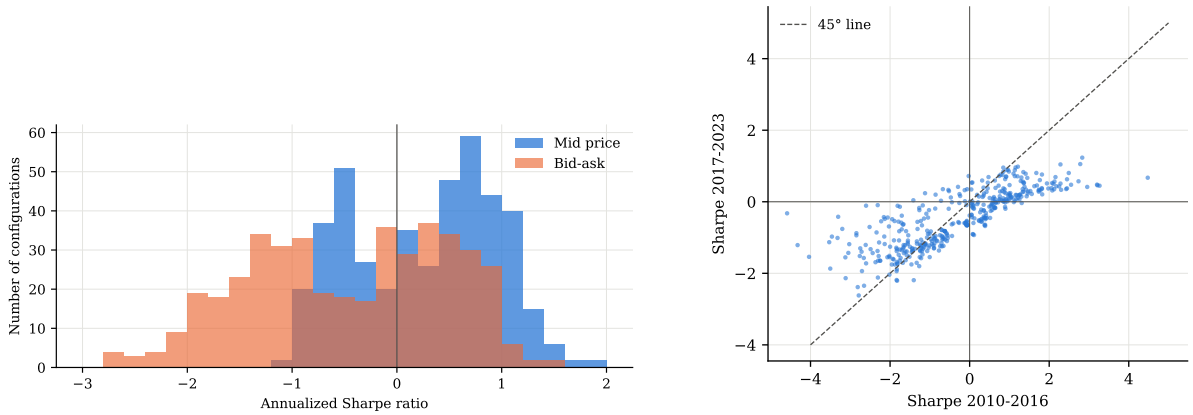

Figure 6: Left: distribution of the Sharpe ratio across the 434 configurations, at mid and bid-ask prices. Right: Sharpe ratio in 2010–2016 and in 2017–2023 for credit configurations.

6.2 Alpha against the index

The share of configurations with positive alpha and a t-statistic above 2 is 16.4% at mid prices and 2.5% at bid-ask prices. Under the null hypothesis of zero alpha for all configurations, the share expected by chance alone is about 2.5%. By contrast, 49.8% of configurations have a significantly negative alpha at bid-ask prices. At prices that can actually be traded, the evidence of return in excess of equity exposure cannot be distinguished from what would be expected in the absence of any capturable premium.

6.3 Ex-post selection

Among 434 configurations the best has a Sharpe ratio of 1.58. The expected maximum under the null, computed following Bailey and López de Prado (2014) from the dispersion of observed Sharpe ratios, is 2.85; the deflated Sharpe ratio of the best configuration is 0.012. The measure is conservative, because the dispersion includes true differences across families and the trials are not independent; it nevertheless indicates that the observed maximum is not, by itself, evidence of a positive expected return.

A more direct check is the sample split. The rank correlation between the Sharpe ratio in 2010–2016 and in 2017–2023 is 0.84: the ordering across families is stable. The level is not: the twenty best configurations in the first period have a mean Sharpe ratio of 2.67 in the first and 0.60 in the second, while the median of all credit configurations in the second period is −0.44. A parameter chosen on the past keeps its relative position and loses about three quarters of the result.

7 Checks on the pre-existing code

The reconstruction required reading the code in the group's repository. The points that change numerical results are reported below, with the file concerned.

1. `vrp_analysis.py` and `utils_vrp_analysis.py`. "Future" realized volatility is computed as `rets.shift(-1).rolling(window=dte).std()`. The rolling window looks backward: the expression uses returns from $t - \text{dte} + 2$ to $t + 1$, that is, past volatility shifted by one session. The "IV minus future RV" charts therefore compare implied volatility with past realized volatility. The correct form is `rets.rolling(n).std().shift(-n)`, with n in sessions.

2. In the same files and in `utils_forecast_price_distribution.py` the time to expiry in calendar days is used as a number of sessions. For an option with 20 calendar days the forecast cumulates 20 daily variances instead of about 14, and the standard deviation of the forecast distribution is overstated by a factor $\sqrt{20/14} \approx 1.20$. The effect is a systematic understatement of the expected value of short structures.

3. In `utils_forecast_price_distribution.py` prices are downloaded up to the expiry date and estimation uses data up to h sessions before the last one: for $h = 20$ the window ends about six sessions before the entry date, and the starting price of the distribution is not the entry price. There is no look-ahead, but forecast and trade are not aligned.

4. In `generate_signal_garch_vs_iv.py` the branch that should generate the long-volatility signal (`spread <= -0.01`) is preceded by the branch `spread < 0.00` and is never executed.

5. In `utils_criteria.py` the `payoff` argument is overwritten at the top of the function by a test vector; the criteria returned do not depend on the strategy passed.

6. The `.gitattributes` file of the main development branch contains an invalid line, the residue of a merge conflict, and the repository's Git LFS quota is exhausted: `.pkl` and `.csv` files can no longer be downloaded. The analyses in this document start from the original compressed archives, which are in the repository without LFS.

The group's historical result on the 10-day iron condor (annualized return of 1.85%, 57.3% winning trades, maximum drawdown above half of capital) is consistent, in sign and order of magnitude, with the results obtained here for the same family.

8 Limitations

Data. Quotes are end-of-day; the spread at the close is wider than the typical intraday spread, and closing prices of options and index may not be synchronous. Monthly expiries with settlement at the open are valued at the close of the expiry day. The sample covers fourteen years of a predominantly rising market.

Margin. The margin of naked positions is approximated by 20% of notional; actual margin depends on the broker and the regime, and under stress it rises just when the position is losing. The series do not include the return on cash collateral.

Design. Every session opens a unit position, with no dynamic sizing. The monthly series assigns the result to the closing month and does not mark open positions to market: intra-month drawdown is understated. Alpha is estimated against the index alone.

Selection. The families and parameters are those the project has explored over the years on the same archive: no part of the sample is truly out of sample. The only uncontaminated check is recording signals before the outcome is known.

9 Conclusions

On SPX chains from 2010 to 2023 the volatility risk premium exists in the form described by the literature: model-free implied variance exceeds realized variance by a large and significant amount, out-of-the-money puts returned about half of the premium to buyers, and the distribution of the realized premium is dominated by a few extreme events. By contrast, there is no significant premium in the sample on at-the-money volatility beyond two weeks: at that level implied volatility is an unbiased forecast of realized volatility and outperforms both the GARCH model and historical volatility. The market appears informationally efficient at the center of the surface and rewards tail risk in the wings.

For the project's strategies there are three consequences. First, symmetric defined-risk structures, the iron condor in particular, sell both the part of the surface that contains the premium (puts) and the part that does not (calls), and pay the spread on four legs; the net result is zero or negative. Second, structures that sell puts keep a positive result after costs, but a material part is equity market exposure and the residual alpha is not statistically distinguishable from zero in the great majority of configurations. Third, exit rules and filters change the distribution of results but do not create expected return; the filter based on the comparison with GARCH has the correct sign and deserves a forward test.

The working hypothesis that the premium exists but that the attempt to capture it systematically tends, over the long run and net of costs, to a zero result is not rejected by the data.

A Payoff at expiry of the structures

With S_T the index value at expiry and premiums in index points, payoffs per unit are as follows. Short put with strike B and premium P_B: $P_B - \max(B - S_T, 0)$. Put credit spread with strikes $A < B$: credit $c = P_B - P_A$, payoff $c - \max(B - S_T, 0) + \max(A - S_T, 0)$, maximum loss $(B - A) - c$, break-even $B - c$. Iron condor with strikes $A < B < C < D$: credit $c = (P_B + C_C) - (P_A + C_D)$, payoff

$$c - \max(B - S_T, 0) + \max(A - S_T, 0) - \max(S_T - C, 0) + \max(S_T - D, 0),$$

maximum loss $\max(B - A, D - C) - c$, break-evens $B - c$ and $C + c$. The iron butterfly is the case $B = C$. For the put calendar with strike K, sold at expiry T_1 and bought at expiry $T_2 > T_1$, the result at the first expiry is $P(K, T_2; T_1) - \max(K - S_{T_1}, 0) - d$, with d the initial debit and $P(K, T_2; T_1)$ the market value of the surviving leg at T_1. All dollar values are obtained by multiplying by 100.
